ABSTRACT

Aim: The maize is widely grown all parts of the world and it is consumed by all people. This paper studies the impact of climate variability on yield of maize crop in Tamil Nadu using Panel regression analysis.

Study Design: Rainfall (max and min), Temperature (max and min) and yield details were collected from the Indian Meteorological Department and crop production reports respectively used for analysis.

Place and Duration: Tamil Nadu, India.

Methodology: Panel data model was used to estimate crop production functions.

Results and Conclusion: The study focused on the impact of climate variability on yield of maize crop in Tamil Nadu using Panel regression analysis. The high rainfall leads to The effect of NEM rainfall on maize yield is dependent on the level of NEM temperature and vice-versa. This is probably because of the fact that in most of the districts in Tamil Nadu, maize is grown as a rainfed crop in north-east monsoon season with lower temperature and hence increase in temperature together with good amount of rainfall would lead to higher yield of maize.

1. INTRODUCTION

Maize is one of the most versatile emerging crops having wider adaptability under varied agro climatic conditions. Maize is also known as the queen of cereals because it has the highest genetic yield potential among the cereals. In India maize is the third most important crop after rice and wheat. In addition to staple food to human being and quality feed for animals, maize serves as a basic raw material for many industries. In developing countries like India, climate change could represent an additional stress on ecological and socioeconomic systems. The Intergovernmental Panel on Climate Change has projected that temperature increase by the end of this century is likely to be in the range 1.8 to 4.0 degree Celsius [1]. Climate change is likely to have larger impacts on predominantly rainfed crops such as maize, coarse cereals and pulses that are grown in marginal production environment. The mean annual temperature over the past four decades from 1971 to 2010 was 31.44°C with a standard deviation of 3.44°C. It has been estimated that in Tamil Nadu, by the end of the 21st century, a 10 per cent decline in rice productivity and a 9 percent decline in sorghum were projected, relative to the average yield during the base period 1971-2009 [2]. The present study has been taken up with the overall objective of analyzing economic impact of climate change on maize crop in Tamil Nadu.

2. MATERIALS AND METHODS

2.1 The Data

Rainfall and temperature were collected from the year 1971 to 2010 for all the districts of Tamil Nadu from Indian Meteorological Department (IMD). The IMD weather stations are not present in all the districts of Tamil Nadu. For the sample districts not having the weather station, we took the averages of climatic data for surrounding districts. The yield data on maize yield was collected crop production reports of Tamil Nadu. Using the districts as panels, panel dataset was constructed using the district-wise time series data available over the period 1971 to 2010.

2.2 Panel Data Model

Gupta et al. studied the impact of climate change on major food grain yields especially in rice, sorghum and pearl millet in India and find significant impacts of climate change (temperature and precipitation) on Indian agriculture [3]. To understand the impact of climate change on maize yield, the panel data model was used to estimate crop production functions. In the present study we have a balanced panel, as each district in the sample has 40 years of observations. The study employed the following model with districts fixed effects and estimated using STATA software:

\[
Y_{it} = \alpha + \theta_i + \beta_1 SWM_{MAXTEMP} + \beta_2 SWM_{MAXTEMP}^2 + \beta_3 SWM_{RFS} + \beta_4 SWM_{RFS}^2 + \beta_5 SWM_{RFS} \cdot SWM_{MAXTEMP} + \beta_6 NEM_{MAXTEMP} + \beta_7 NEM_{MAXTEMP}^2 + \beta_8 NEM_{RFS} + \beta_9 NEM_{RFS}^2 + \beta_{10} NEM_{RFS} \cdot NEM_{MAXTEMP} + U_{it}
\]

Where,

- \( Y_{it} \) = Yield of maize crops in district \( i \) in year \( t \)
- \( SWM_{MAXTEMP} \) = South West Monsoon Maximum Temperature in degree Celsius
- \( SWM_{MAXTEMP}^2 \) = Squared South West Monsoon Maximum Temperature in degree Celsius
- \( SWM_{RFS} \) = South West Monsoon Rainfall in Millimeter
- \( SWM_{RFS}^2 \) = Squared South West Monsoon Rainfall in Millimeter
- \( SWM_{RFS} \cdot SWM_{MAXTEMP} \) = Interaction term (SWM Rain* SWM Maximum Temperature)
- \( NEM_{MAXTEMP} \) = North East Monsoon Maximum Temperature in degree Celsius
- \( NEM_{MAXTEMP}^2 \) = Squared North East Monsoon Maximum Temperature in degree Celsius
- \( NEM_{RFS} \) = North East Monsoon Rainfall in Millimeter
- \( NEM_{RFS}^2 \) = Squared North East Monsoon Rainfall in Millimeter
- \( NEM_{RFS} \cdot NEM_{MAXTEMP} \) = Interaction term (NEM Rain* NEM Maximum Temperature)
- \( U_{it} \) = Error term

\( \theta \) and \( \beta_1 \) to \( \beta_{10} \) are unknown parameters to be estimated.

2.3 Hausman Specification Test for Fixed vs. Random effects model

To decide between a random effects and fixed effects model, the Hausman specification test was performed. Gupta et al. studied the impact of climate change on major food grain yields especially in rice, sorghum and pearl millet in India with district and year fixed effects, and district fixed effects and district-by-year fixed effects [3]. The Hausman test is designed to detect violation of the random effects modelling assumption that the explanatory variables are orthogonal to the unit effects. If there is no correlation between the independent variable(s) and the unit effects, then estimates of $\beta$ in the fixed effects model ($\beta_{FE}$) should be similar to estimates of $\beta$ in the random effects model ($\beta_{RE}$).

The Hausman test statistic ($H$) is a measure of the difference between the two estimates:

$$H = (\beta_{RE} - \beta_{FE})[\text{Var}(\beta_{FE}) - \text{Var}(\beta_{RE})]^{-1}(\beta_{RE} - \beta_{FE})$$

Under the null hypothesis of orthogonality, $H$ is distributed chi-square with degrees of freedom equal to the number of regressors in the model. A finding that $p < 0.05$ is taken as evidence that, at conventional levels of significance, the two models are different enough to reject the null hypothesis, and hence to reject the random effects model in favour of the fixed effects model. If the Hausman test does not indicate a significant difference ($p > 0.05$), however, it does not necessarily follow that the random effects estimator is safely free from bias, and therefore to be preferred over the fixed effects estimator.

3. RESULTS AND DISCUSSION

3.1 Results of Panel Data Model

The impact of climate variables on maize production was also estimated using district level panel data, with the districts serving as panels. Descriptive statistics of the variables used in the panel data model are presented below followed by the results of fixed effects panel data regression model.

3.2 Descriptive Statistics

The summary statistics of the climate and crop yield variables used in the analysis are presented in Table 1. The average productivity of both maize was about 1800 kg/ha and the standard deviation of maize yield was 1065 kg/ha. The mean level of annual rainfall over the 40 years was 965.56 mm per year with a standard deviation of 343 mm. The maximum temperature was 35.26°C and the minimum temperature is 30.53°C. World Bank notes that frequency of heavy precipitation events has increased over most land areas and widespread changes in extreme temperatures has been recorded over the last 50 years [4].

3.3 Fixed Effects versus Random Effects Model: Hausman Specification Test

The Hausman specification test was performed to select appropriate model.

The Hausman test is designed to detect violation of the random effects modeling assumption that the explanatory variables are orthogonal to the unit effects. If the Chi-square value is significant (<0.05) then, reject the null hypothesis, and hence to reject the random effects model. Based on the results of Hausman specification test, the fixed effects model has been employed for the study. The results of Hausman specification test are presented in Table 2.

3.4 Results of Panel Regression Model with Fixed Effects for Maize

Table 3 presents the results of panel regression with districts fixed effects for maize.

Adamgbe and Ujoh studied the variations in climatic parameters and crop yield in Nigeria. The result showed that the seven climatic parameters (onset and end of the rains, duration of rainy season, rain days, annual amount, temperature and sunshine) jointly accounted for 78% of variance in yam yield, about 71% of variance in cassava and sorghum yields, 60% of variance in soya beans yield, 49% of variance in maize yield, 48% of variance in rice yield and 36% of variance in groundnut [5]. The sign of the regression coefficient of SWM maximum temperature was positive and its quadratic term was found to be negative at five per cent level of significance, which means that an increase in south west monsoon temperature will increase the yield of maize up to a threshold level beyond which the yield will decrease. All the climatic variables during north east monsoon were significant at one percent level except the NEM rainfall quadratic term (ten per cent). The partial regression coefficient of NEM rainfall and its quadratic term were found to be negative, which means that the increasing rainfall during the season will decrease the maize yield.

The coefficient of the NEM maximum temperature was negative and it was positive for its quadratic term, which indicates that the maize yield has a U-shaped response function with NEM maximum temperature. Higher temperature would mean lower yield rates though at a decreasing rate. In case of the interaction terms, the north east monsoon shows positive sign with one per cent significance level and it was negative in south west monsoon with five per cent significance level. The effect of NEM rainfall on maize yield is dependent on the level of NEM temperature and vice-versa. Sultan et al. assessed the climate change effects on sorghum and millet yields and found that, the major effect of climate change on the yields of millet and sorghum in West Africa was yield losses induced by higher temperature leading to increased potential evapotranspiration, crop maintenance respiration and a reduction of the crop-cycle length [6]. This is probably because of the fact that in most of the districts in Tamil Nadu, maize is grown as a rainfed crop in north-east monsoon season with lower temperature and hence increase in temperature together with good amount of rainfall would lead to higher yield of maize.

4. CONCLUSION

The study focused on the impact of climate change on yield of maize crop in Tamil Nadu using Panel regression analysis. Based on the results of Hausman specification test, the fixed effects model has been employed for the study. The effect of NEM rainfall on maize yield is dependent on the level of NEM temperature and vice-versa. The regression coefficient of SWM maximum temperature was positive and its quadratic term was found to be negative at five per cent level of significance, which means that an increase in south west monsoon temperature will increase the yield of maize up to a threshold level beyond which the yield will decrease. This is probably because of the fact that in most of the districts in Tamil Nadu, maize is grown as a rainfed crop in north-east monsoon season with lower temperature and hence increase in temperature together with good amount of rainfall would lead to higher yield of maize. Climatic factors viz., temperature and rainfall were very important in the impact of maize yield. Thus maize yield will increase when the increase in temperature along with the increase in rainfall.
